The network autocorrelation model has been a workhorse for modeling network influences on individual behavior. The standard network approaches to mapping social influence using network measures, however, are limited to specifying an influence weight matrix (W) based on a single mode network. Additionally, it has been demonstrated that the estimate of the autocorrelation parameter ρ of the network effect tends to be negatively biased as the density in W matrix increases. The current study introduces a two-mode version of the network autocorrelation model. We then conduct simulations to examine conditions under which bias might exist. We show that the estimate for the affiliation autocorrelation parameter (ρ) tends to be negatively biased as density increases, as in the one-mode case. Inclusion of the diagonal of W, the count of the number of events participated in, as one of the variables in the regression model helps to attenuate such bias, however. We discuss the implications of these results.

Social Network Analysis (SNA) has been widely used to measure the degree of social influences on behavior change based on social theory. SNA has been used to model various forms of network influence on individual behavior using the so-called network autocorrelation model (Doreian, 1980a, 1981, 1990; Dow, 2007; Dow et al., 1984; Leenders, 2002; Mizruchi and Neuman, 2008; Ord, 1975; Paez et al., 2008; Smith, 2004). It has been a workhorse for modeling theories of social influence by measuring and statistically testing network effects on individual behaviors. Similarly, in diffusion of innovation studies, the network exposure model (Burt, 1987; Marsden and Friedkin, 1993; Valente, 1995, 2005) has been widely employed to measure the extent to which individuals are exposed to an innovation in the network, which is then presumed to influence the timing of his or her adoption of innovation. The network exposure model can be used to model behavioral outcomes as being influenced simultaneously by local- and network-level effects and provides a mapping of social theories with statistical estimation (Leenders, 2002) by specifying the appropriate weight matrix (W) for different network influence processes (Valente, 1995).

The standard network approaches for mapping social influence have been limited in their operationalization by specifying a weight matrix W based on a single mode (actor-by-actor) network. W is a N × N weight matrix with elements wij representing the extent to which actor j (alter) influences actor i (ego). For example, research using network exposure to substance use has shown a correlation between individual use and exposure to friends’ use of substances (Alexander et al., 2001; Cleveland and Wiebe, 2003; Cleveland et al., 2005; Crosnoe, 2002, 2006; Crosnoe et al., 2004; Hall and Valente, 2007; Haynie, 2001). Peer influence based on friendship relations, however, is only one of the many ways peers come into contact with one another and potentially influence each other’s behavior.

In this paper, we extend the existing one-mode network exposure model by developing a new influence model of “affiliation exposure” that statistically tests the affiliation effect within a network autocorrelation framework. We believe this new model will allow analysis of social influences previously not available with network exposure type models, and thus opening entirely new information vistas for exploration and examination. In the proposed “affiliation exposure model,” the weight matrix W is the converted affiliation matrix using the off-diagonal values of the co-membership matrix. The diagonal of the converted matrix (i.e.,
the number of events participated in by each actor) is used as a covariate in subsequent regression analysis. It is known that the one-mode network autocorrelation model contains potential biases in the estimation of the structural parameter (Dow et al., 1982; Mizruchi and Neuman, 2008; Neuman and Mizruchi, 2010; Paez et al., 2008; Smith, 2004, 2009) under certain conditions. In particular, a recent simulation study has shown negative bias in the estimate of the autocorrelation parameter $\rho$ (i.e., estimated $\rho$ tends to be lower than the population $\rho$) and this tendency becomes more pronounced with higher density in random graphs (Mizruchi and Neuman, 2008). This bias is reported to hold across other types of well-known networks including the star, caveman, and small-world structures (Neuman and Mizruchi, 2010).

Given these results, we decided it was prudent to see if a similar bias was present in the affiliation exposure model, and so we have conducted a simulation study to examine the statistical bias in the maximum likelihood (ML) estimates of autocorrelation parameter $\rho$. To maximize our ability to compare our results with prior reports, we have chosen to match many of the independent parameters of the simulation performed earlier by Mizruchi and Neuman (2008). Given the bias observed in the one-mode autocorrelation model, we will explore potential bias in the two-mode version of the network effects model, i.e., a bias in the autocorrelation parameter $\rho$ for affiliation exposure. As in the one-mode case, we will investigate the network density levels at which bias in the autocorrelation parameter potentially become pronounced.

In this study, two-mode actor-by-events bipartite graphs were randomly generated based on a Poisson-distributed outdegree (i.e., conditioning on the expected number of events, $\lambda$, for each actor which is the mean number of events each actor participated in). Using a range of different densities of simulated bipartite graphs, along with varying levels of network autocorrelation $\rho$ and event total local effect $\gamma$, we explore the extent to which the density of the affiliation network affects the degree of bias in the parameter estimates derived from the model. We will show that the autocorrelation parameter tends to be biased with increased density, and this negative bias becomes increasingly pronounced as $\gamma$ (the main effect of event participation) approaches zero. We will conclude by discussing the implications of our findings for estimating affiliation exposure models, and how including the diagonal (out-degree) values seem to help stabilize the estimates (in the presence of noise) of the model and helps mitigate the systemic negative bias.

This study conceptualizes social influence based on co-membership in organizations, events, or activities, and proposes a new way of operationalizing affiliation-based network influence derived from two-mode network data within a network autocorrelation modeling framework. It assumes that co-membership is a structural feature that defines individual social identities and increases the probability of forming acquaintances (McPherson, 1982). Affiliation-based social influence is conceptually different from friends’ influence in that it assumes that social influence is not limited to positive-affective ties. Borgatti and Everett (1997), in their discussion of classic women-by-event affiliation data (A. Davis et al., 1941), pointed out that the strength of social proximity of a pair of women who attended the same events reflects not only a positive-affective tie but also a non-liking/negative-affective tie (i.e., having a competitive relationship), thus still being closely familiar with and influenced by each other (p. 246).

1. Two-mode network data

In SNA, structural variables are measured based on a distinct set of entities, which are referred to as “mode” (Wasserman and Faust, 1994). In the one-mode network, structural variables are measured on a single set of nodes (N) within a given network boundary, and network data are represented as a sociomatrix X, composed of N rows (nominating nodes) and N columns (receiving nodes), with elements of $X_{ij}$ equal to 1 if a node i (row) nominated a node j (column) as a given relation, and 0 otherwise.

In the two-mode network data, structural variables are measured on two sets of nodes. Usually, the first mode is a set of actors within a given network boundary, and the second mode is a set of events with which the actors in the first set are affiliated. Such two-mode networks are referred to as affiliation networks with each actor (indexed in row) with each event (indexed in column) in the $N \times K$ matrix form $A_{ij}$, with the entry $A_{ij}$ equal to 1 if row actor $n_i$ is affiliated with column event $j$, and 0 otherwise. Two-mode network or affiliation networks are also referred to as bipartite graphs, membership networks (Breiger, 1974), or hypernetworks (McPherson, 1982).

2. Analysis of affiliation networks

There are primarily two current approaches to analyzing affiliation networks. The first approach is to analyze the two-mode network data directly without transformation. Many studies have developed such techniques to analyze “raw” two-mode networks including Q-Analysis (Doreian, 1980b; Freeman, 1980), Galois lattices (Freeman and White, 1993; Roth and Bourgine, 2005; Wasserman and Faust, 1994), correspondence analysis (Faust, 2005; Roberts Jr., 2000), blockmodeling (Doreian et al., 2004), centrality measures (Bonacich, 1991; Borgatti and Everett, 1997; Faust, 1997), overlapping membership (Bonacich, 1978), structural similarity (Borgatti and Everett, 1992), clustering (Borgatti and Everett, 1997; Robins and Alexander, 2004), degree distributions (Newman et al., 2001, 2002; Robins and Alexander, 2004), exponential random graph models (Aegeessens et al., 2004; Faust et al., 2002; Skovoretz and Faust, 1999; Wang et al., 2009), and identification of positions (Field et al., 2006).

The second approach for studying two-mode networks is to convert the data into two (or more) one-mode networks, either as an actor-by-actor network or an event-by-event one. The process of converting a two-mode network into its one-mode versions is frequently described as the projection of the bipartite graph onto the unipartite space of actors or events only. In a projected actor-by-actor matrix, each pair of actors is connected if they share at least one common event. In particular, these one-mode “projection” networks are frequently constructed by either multiplying the affiliation $(N \times K)$ matrix $A$ with its transpose (i.e., $A^T$) or multiplying the transpose of the affiliation matrix with itself (i.e., $A^T A$). The resulting converted matrices are symmetric, valued, 1-mode matrices that record the co-membership relation for each actor $(N \times N$ matrix $C = A^T A$) or the overlapping relations for each event $(K \times K$ matrix $T = A^T A$). Essentially, in the individual, actor-by-actor case the co-membership (C) off-diagonal entries count the number of events jointly affiliated with for each pair of actors, and the diagonal entries count the total number of events each actor is affiliated with. In the event-by-event case the off-diagonal entries count the total number of actors jointly affiliated by each pair of events, and diagonal entries count the total number of actors affiliated with each event. To date, the projected one-mode networks are usu-
ally dichotomized,\textsuperscript{4} and then analyzed using conventional network analytic techniques.

Using either of the two approaches described above, various types of collaboration networks have been studied that include: the networks of movie actors where two actors are linked if they co-appear in the same movie (Watts and Strogatz, 1998), the networks of scientists where two scientists are linked if they co-author a paper (Newman, 2001a,b,c), the network of words where two words are linked if they co-occur in the same sentence (Ferrer and Sole, 2001), the interlocking networks of board of directors where two directors are linked together if they are members of the same board (Conyon and Muldoon, 2004; G. F. Davis and Mizruchi, 1999; Mizruchi, 1996; Robins and Alexander, 2004). Additionally, some other network studies have conducted combined analysis of bipartite graphs with projections of them (Guillaume et al., 2004; Latapy et al., 2008; Newman et al., 2001; Robins and Alexander, 2004) to examine how network features differ between two methods.

It is generally accepted, however, that directly analyzing bipartite graphs provides a richer understanding of two-mode structures than analysis using the projected 1-mode data only, since much information in the original bipartite structure (such as information about path lengths of three or more and information about nodes with a single affiliation) is lost during the projection process (Latapy et al., 2008; Robins and Alexander, 2004; Wang et al., 2009). Nonetheless, using the projected 1-mode matrix is appropriate when theoretical attention is being focused on one type of the two social entities (Robins and Alexander, 2004) and primary interest lies in how the actors/events are connected via the events/actors (Borgatti and Everett, 1997).

The analysis presented here is based on a projected, non-binarized one-mode analysis that focuses on the actor-to-actor network (AA, rather than the event-to-event network A/A) since our theoretical attention is on the actors rather than the events, and thus our primary interest lies in the co-membership among actors via the events. This co-membership is the backbone of modeling the affiliation-based social influence within a network autocorrelation framework where the unit of analysis is the individual actor, but before introducing the affiliation exposure model, the following section will review the general formula of a network exposure model for one-mode data.

3. Network exposure model

The general formula of the network exposure $E$ (for $N$ actors) has been introduced and developed (Valente, 1995, 2005), which is defined as:

$$E = \frac{\sum_{j=1}^{N} W_{ij} Y_j}{\sum_{j=1}^{N} W_{ij}} \quad \text{for} \quad i, j = 1, \ldots, N \quad i \neq j$$ (1)

where $E$ is the $N$-by-$1$ exposure vector, $W$ is a social network weight matrix, and $Y$ is a vector of $j$’s behavioral attribute ($j = 1, \ldots, N$; $j \neq i$). By specifying different weight matrices $W$, the general exposure model measures different types of social influence. There have been two contrasting one-mode network approaches to studying social influence and measuring interpersonal proximity, (1) “structural cohesion” which measure direct and indirect connectivity among actors and (2) “structural equivalence” which measures network positions in terms of the similarity of actors’ profiles of relations (Burt, 1987; Marsden and Friedkin, 1993; Valente, 1995).

Social influence based on cohesion is founded on solidarity relations such as friendship or advice relations (Marsden and Friedkin, 1993) and presumes that individuals are influenced by other actors in the network with whom an individual has direct ties. This type of social influence is termed “relational exposure” (Valente, 1995), which is computed by using a one-mode adjacency matrix, $X$, as a specification of weight matrix $W_{ij}$, with $X_{ij} = 1$ if an actor $i$ nomi- nates an actor $j$ in a given positive relationship, and $X_{ij} = 0$ otherwise. By multiplying $X_{ij}$, by nominated actors’ behavior $y_j$ and normalizing by the row-sum of $X_j$ (i.e., $\tilde{y}_j$), the resulting normalized relational exposure of $E$ measures the mean level of nominated actors $j$s who have behavioral attribute of $y_j$ in an ego network.

On the other hand, social influence based on structural equivalence emphasizes competition between ego and alter. The more similar two people are in the network, the more substitutable they are and this may lead to increased feelings of competition. It has been shown that individuals are more likely to adopt innovations as their structurally equivalent alters adopt (Burt, 1987). People who occupy similar structural positions (in terms of patterns of relations with all other actors in the network) will influence each other, and this type of social influence is termed as “positional exposure” (Valente, 1995). “Positional exposure” is calculated by using the one-mode adjacency matrix of $X_j$, to compute structural equivalence matrix of $S_j$ that is based on any of the profile similarity relations between all pairs of actors.\textsuperscript{5} Although social influence based on structural equivalence extends the frame of reference ego’s neighbors to the network as a whole, it is still limited to conceptualizing social influence based on one-mode social network data. It should be noted that various coding schemes can be considered in defining the weight matrix $W$ (Tiefelsdorf et al., 1999). For the simplicity of interpretation, the most frequently used row-sum standardization, or W-coding scheme, was used in this study.

4. Development of the affiliation exposure model

We now introduce a new way of conceptualizing social influence based on co-membership with events, and we call this type of social influence “affiliation exposure” (Fujimoto et al., forthcoming). In the specification of $W_{ij}$ in the network exposure model, “affiliation exposure” uses the converted one-mode matrix $C_+ AA'$ that records the co-membership relations (i.e., the number of events each pair of actors attended in common) in a network, thus representing the affiliation-based social influence. The diagonal is the count of the number of events each actor is affiliated with and this is extracted for inclusion in the subsequent statistical network autocorrelation analysis as an independent variables (discussed later). The diagonal is set to zero in the calculation of exposure. By multiplying $C_j$ by each co-participant’s attribute $y_j$ and normalizing it by row-sum $C_j$ (ignoring the diagonal), the resulting affiliation exposure vector of $F$ is defined as follow:

$$F = \frac{\sum_{j=1}^{N} C_{ij} y_j}{\sum_{j=1}^{N} C_{ij}} \quad \text{for} \quad i, j = 1, \ldots, N \quad i \neq j$$ (2)

Affiliation exposure, $F$, measures the degree each actor is exposed to attribute $Y$ based on the extent of co-participation among the

\textsuperscript{4} There are some exceptions that do not dichotomize a projected one-mode network. For example, Bonacich developed a measure of structural centrality in the pattern of overlapping memberships (independent of group size), which uses a continuous measure of association (Bonacich, 1972).

\textsuperscript{5} There are various ways to measure the profile of similarity including ones based on the proportion of exact matches (the “Exact” method), based on the proportion of exact matches of only non-zero values (the “Jaccard” method), and based on the distance between profile vectors with the root of the sum of squared differences (the “Euclidian distance” method).
actors. More specifically, the affiliation exposure measures the mean level of attribute of \( y_i \) that is weighted by the proportion of all events each pair of actors co-participated in. For example, if an actor participated in three events with one alter, and a single event with another alter, then the first alter’s influence (“exposure”) is three times greater than the second alter’s influence. In the next section, we situate the affiliation exposure term within the network autocorrelation framework, and examine potential bias of network autocorrelation parameters and local event parameter estimates for various levels of density in the converted matrix \( C \).

5. Network autocorrelation model

In the standard linear OLS regression model, \( y = X\beta + \epsilon \), random variable of error term is based the assumption of being independently and identically distributed (i.i.d.) with mean zero and equal variances, \( \sigma^2 \). However, in the analysis of network data, the independence assumption for the error terms is violated due to correlation among error terms. The network autocorrelation model (Doreian, 1980a, 1981, 1990; Dow, 1984; Ord, 1975) was developed to deal with the issue of the network autocorrelation in the regression analysis. There have been two families of network autocorrelation models, which are (1) network effects model and (2) network disturbances model. This study uses the network effects model (Doreian et al., 1984) which is more straightforward to model social influence than the network disturbances model (Doreian, 1980a; Dow et al., 1984; Ord, 1975).\(^6\) The network exposure model assumes that social influence occurs when individuals are exposed to a behavior by their network contacts. The exposure is estimated via the network effect model. Network effects model is based on the assumption that social influence occurs through the dependency among responses to the dependent variable (Leenders, 2002). It treats the network autocorrelation as a parameter and models the autoregressive effects on outcome variable:

\[
y = \rho W y + X\beta + \epsilon, \quad \epsilon \sim N(0, \sigma^2) \tag{3}
\]

where \( y \) is a \((N \times 1)\) vector of values for a dependent variable, \( X \) is an \((N \times h)\) matrix of values for the \( N \) actors on \( h \) independent variables with unit row vector for the intercept term, \( \beta \) is a \((h \times 1)\) vector of regression coefficients, \( \rho \) is a scalar estimate of autocorrelation parameter, and \( W \) is a \((N \times N)\) weight matrix with its element \( w_{ij} \) representing the degree to which \( y_i \) depends on \( y_j \). The \( W \) matrix can be row or column normalized to unity,\(^7\) which determines how social influence is allocated among alters in the network, thus altering the strength of influence for a particular influence (Leenders, 2002). It is important to note that in relation to the network exposure model, \( Wy \) term with row-normalized \( W \) matrix corresponds to the values of exposure term \((E)\) defined in the Eq. (1).

The network effect model for affiliation exposure is defined as:

\[
y = \rho W y + X\beta + \gamma D + \epsilon, \quad \epsilon \sim N(0, \sigma^2) \tag{4}
\]

where \( y, X, \beta, \rho, \) and \( \epsilon \) are defined as in Eq. (3). \( W \) is equivalent to \( F \) in Eq. (2) with \( W \) being a \((N \times N)\) row-normalized co-membership

---

\(^6\) Network disturbances model is defined as: \( y = X\beta + \epsilon = \rho W e + v, \quad v \sim N(0, \sigma 2 I) \), where \( y, X, \beta, \) and \( \epsilon \) have been defined in the Eq. (3). Here, \( e \) is an \((N \times 1)\) column vector of error terms that is a weighted average of the disturbances, \( \rho \) is now a parameter that represents the degree to which the error terms are correlated, and \( v \) is an \((N \times 1)\) column vector of random residuals that is independently normally distributed given the removal of the correlated errors into \( \rho W e \) (Mizruchi and Neumann, 2008). Network disturbances model is based on the assumption that social influence occurs through the autocorrelation of the disturbances (Leenders, 2002), and models disturbances as being affected by network autocorrelation.

\(^7\) A new stochastic matrix \( W \) can be obtained by being divided by its row/column sum, where \( w_{ij} = w_{ij} / \sum_i w_{ij} \) for column-normalization.

---

\(^8\) For network autocorrelation model, the standard ordinary least squares (OLS) method yields biased and inconsistent estimates of both autocorrelation parameter \( \rho \) and regression parameter \( \beta \) since \( W y \) variable and the error term, \( \epsilon \), are correlated (Dow, 2007; Johnston, 1984). To overcome this problem, other estimation methods were proposed including maximum likelihood estimation (MLE) procedure, two-stage least squares estimation (2SLS) procedure (Anselin, 1990; Dow, 2007; 2008; Gelejean and Prucha, 1998; Land and Deane, 1992), and Bayesian estimation (LeSage, 1997).
Density in the affiliation network $A$ is computed using the following formula (Borgatti and Everett, 1997): $\lambda_{ij} > 0$ for $i, j = 1, \ldots, N$ and $i \neq j$

In other words, we are using the average normalized out-degree score, and this is mathematically equivalent to other common one-mode (binary) density calculation formulations. The density of $C$ $(\lambda_{ij})$, however, is, in part, a function of the expected number of events each actor participated in (i.e., Poisson parameter $\lambda$) but they are not linearly related, which prevented us from obtaining a closed-form solution. Therefore, we have instead employed a linear-interpolation approach to obtaining an estimate of the needed lambda ($\lambda$) values for the desired densities in $C(\lambda_{ij})$ within ±1%. We will discuss this procedure in more detail in the next section.

6.1. Generating random bipartite graph

Our simulation uses a Poisson outdegree distribution\(^{10}\) with parameter $\lambda$ to generate random bipartite graphs $A$, where a random variable of $A_{ij}$ (sum of row $i$ of matrix $A$) represents the number of events participated in for an actor $i$ ($i = 1, \ldots, N$), and the expected number of events each actor participated becomes $E(A_{ij}) = \lambda$. We have chosen the Poisson outdegree distribution since we assume a homogeneity in the distribution (i.e., no actors are very different from the average number of events participated in), indicating the normal and expected behavior when taking an actor at random\(^{11}\) (Latapy et al., 2008). Additionally, these values are based on several empirical affiliation studies which reported the average number of organized sports activities participated in ($K = 13$) by middle-school students ($N \geq 100$), which approximated a Poisson distribution.

There are two steps to generate the random bipartite graphs used in this study.\(^{12}\) First, we generated binary actor-by-event bipartite graphs drawn uniformly at random constrained on

---

\(^{9}\) Density in the affiliation network $A$ is computed using the following formula (Borgatti and Everett, 1997): $\lambda_{ij} > 0$ where $L$ is the number of ties present in the affiliation network $A$ and the denominator ($N \times K$) represents the maximum number of ties possible in the affiliation network $A$, i.e., every actor is connected to every event.

\(^{10}\) We did not specify the indegree distribution (the number of actors affiliated with a given event) since we theoretically focus on the mode of actors rather than the other mode of events as unit of analysis, prioritizing the specification of outdegree distribution in actor-by-event bipartite graphs (i.e., the event total affiliated by each actor) that are controlled as one of the covariates in network autocorrelation model.

\(^{11}\) This is different from an assumption of a heterogeneous distribution where a significant number of actors are very different from the average one, such as that used in the case of a power-law distribution (Latapy et al., 2008).

\(^{12}\) Our method of generating random bipartite graphs is different from previous simulation studies that used empirical affiliation data as the basis of comparison. Examples include generating uniform random bipartite graphs distributions conditionally on properties of the infrastructure of the empirical data using a bootstrap approach (Robins and Alexander, 2004), generating random bipartite graphs with the same size and the same degree distributions (Latapy et al., 2008), mathematically deriving exact generating functions for the probability distribution of vertex degrees (Newman et al., 2001, 2002). Our simulation study does not employ specific empirical data to generate random bipartite graph since this paper aims at providing general model and exploration of biasness of its parameters if any, and is not limited to a specific substantive issue or data.
Poisson outdegree distribution with densities (in A matrix) ranging from 0.05 to 0.95 in increments of 0.05. For each targeted density value, we generated 100 random bipartite graphs. Then, we converted these observed random bipartite graphs into one-mode co-membership matrices and computed corresponding densities (by using $\Delta(c)$). Fig. 1 shows the non-linear relationship between the theoretical density values (as determined by $\lambda$ divided by event size) and the actual observed densities in $C$ for a variety of $K$ values (event size) and 100 actors.

Since the simulation will treat the density of the $C$ matrix as one of the independent parameters, we compensated for the non-linear relationship shown in Fig. 1(a) by interpolating a “corrected” density parameter for the $A$ matrix such that the corresponding $C$ matrix density ($\Delta(c)$) would match the target value. The result of this process is shown in Fig. 1(b) example in which $K=20$ and 100 actors. The targeted (x-axis) and observed densities (y-axis) now match within $\pm1\%$ (solid green line). For illustrative purposes, the dotted red line shows the density of $A$ required to reliably generate the targeted density in the $C$ matrix. In other words, simply incrementing by fixed amounts of the average number of events in the simulated affiliation networks does not provide correspondingly incremental densities in the resulting $C$ matrix. As an example, to obtain a target density of $\Delta(c) = 0.15$, a density of 0.37 (see Fig. 1b) in the affiliation matrix must be generated, which required a corresponding $\lambda$ value of 6.08 on a matrix with 100 actors and 20 events. In the second step, we generated 100 random bipartite graphs at each target density level ($\Delta(c)$) using the corresponding estimated $\lambda$ values, and these were the graphs used in the subsequent analysis (parameter specification will be discussed later).

### 6.2. Simulation procedures

Our simulation procedure\textsuperscript{14} was implemented as follows:

\textsuperscript{13} Note the value $\lambda$ is dependent on both the number of actors and the number of events.

\textsuperscript{14} Our simulation study is in line with previous network autocorrelation simulation studies conducted in the case of one-mode networks (Mizruchi and Neuman, 2008; Neuman and Mizruchi, 2010), rather than studies that directly measure and test bipartite statistics.
Step (1): Number of actors is 100, and the maximum number of events is K=10 (thus forming a 100-actor by 10-events affiliation matrix A).

Step (2): Targeted density, $\Delta_{ij}$, in the $(100 \times 100)$ co-membership matrix $C(\Delta_{ij})$ was initiated at 0.05 and incremented by 0.05–0.90 with corresponding estimated $\lambda$ values to be $(1.80, 2.56, 3.16, 3.65, 4.10, 4.54, 4.93, 5.29, 5.66, 6.03, 6.35, 6.69, 7.07, 7.48, 7.81, 8.18, 8.61, 9.06)$.

Step (3): We randomly generated three covariate variables $X$ plus the unit vector for the intercept term and corresponding set of regression coefficients (three $\beta$ values plus an $\alpha$ value) from a standard normal distribution (with a mean of 0 and standard deviation of 1). We have also specified a vector of error term $\epsilon$ drawn from a standard normal distribution with mean zero and standard deviation of $\sigma = 1.0$. However, the previous study indicated that negative bias could be attributed to the specification of model noise in the simulation by showing that reduction in the variance of the residuals (i.e. and thus improving the fit of the models) by setting the standard deviation ($\sigma$) of the residuals from unity to 0.1 contributed significantly to remove most of the bias in the sampling distributions of $\rho$ (Mizruchi and Neuman, 2008). Therefore, the present simulation specified $\sigma = 1$ (since it is a more conservative approach) and also a $\alpha = 0.1$. Additionally, the diagonal entries of $C$ matrix (i.e., $C_{ii}, i=j$) were constructed to estimate event total effect, which was defined as the $D$ term in the network effects model.

Step (4): The population (true) value of the autorecorrelation parameter ($\rho$) was set to $\{-0.8, -0.5, -0.2, 0.0, 0.1, 0.2, 0.5, 0.8\}$ and the population event total parameter ($\gamma$) was set to $\{0.0, 0.25, 0.5, 0.75, 1.0\}$. We used combinations of $\rho$, $\gamma$, $\Delta_{ij}$ for the parameter space to be simulated. For each combination we performed a trial by running 100 replications of our model, which yield $9(\rho) \times 5(\gamma) \times 18(\Delta_{ij}) \times 100$ (replications), yielding a total of 81,000 individual model runs.

---

We selected the population parameters $\rho$ to be consistent with one-mode simulation conducted by Mizruchi and Neuman (2008).
Step (5): We computed the “observed” values of \( Y \) in our network effects model by transforming the equation
\[
y = \rho \beta_3^ T X + \epsilon_D + \epsilon
\]
to
\[
y = (1 - \rho \beta_3^ T X) + \epsilon_D + \epsilon
\]
and then inserting the simulated \( W \), the three \( X \) variables and intercept unit vector as well as their corresponding coefficients \( \alpha \) and three \( \beta \), the residuals \( \epsilon \), and a set of assigned population autocorrelation parameters \( \rho \), and the population event parameter \( \gamma \).

Step (6): We returned to the original autocorrelation model
\[
y = \rho \beta_3^ T X + \epsilon_D + \epsilon
\]
and used this \( y \) along with \( W \), \( X \), and \( D \) to estimate the model parameters of \( \rho \) (and \( \gamma \)). If these estimated parameters are unbiased, then the value of \( \rho \) (and \( \gamma \)) computed from these trials should have a sampling distribution with a mean approximately equal to the originally specified population value (Mizruchi and Neuman, 2008).

For step (1) we employed the MATA programming language in STATA to generate the random bipartite graphs conditioned on Poisson outdegree distributions and then exported these matrices to the R environment to perform the remaining steps, using the “Inam” function in the “sna” package program (Butts, 2008) for steps (4) and (5) in a manner similar to (Mizruchi and Neuman, 2008).

7. Results

For the first set of results, we report three-dimensional (3D) graphs of the simulation results to observe some overall trends.
Table 2
For the disturbance specification of $\sigma = 1.0$ and $K = 20$, the statistics of the sample means of the estimated $\rho$ and corresponding $95\%$ confidence intervals around the means for 100 replications are reported.

<table>

</tbody>
</table>

Fig. 2 shows graphs of the mean difference between estimated $\rho$ and the population $\rho = (\Delta \rho)$ as a 3D-surface against the varying density level and population gamma $\gamma$ values for each population value of $\rho (\rho = -0.8, -0.5, -0.2)$ going from left to right in the upper row, $\rho = -0.1, 0.0, 0.1$ going from left to right in the middle row and $\rho = 0.2, 0.5, 0.8$ going from left to right in the lower row.

All of these graphs display a general tendency that the surfaces tilt toward the corner of higher density values and lower variance in the population of $\gamma$ (For interpretation of the references to color in the text, the reader is referred to the web version of the article). These results imply that there is a negative bias tendency to the autocorrelation parameter as density increases and as $\gamma$ population decrease (approaches zero) for all levels of $\rho$. The first observation (the density effect) is consistent with a similar observation for the one-mode case as reported by Mizruchi and Neuman (2008). The second observation (i.e., less negative bias for higher values of $\gamma$) makes sense since D (which is not as random as the other terms given its relation to $W$) has a stable underlying structure that helps reduce the final variance in the estimates and thus stabilize the system as a whole. The stabilizing effect of $D$ increases as $\gamma$ approaches one, and leads to a better fit of the model and reduction in variance.
tion in the final variance of the residuals. To explore these results in more detail, we have drawn two-dimensional graphs with both specifi-
cations of the standard deviation of error term i.e., $\sigma = 1.0$ and
$\sigma = 0.1$.

Fig. 3 shows the mean plots of the estimated autocorrelation
parameter $\rho$ among 100 replications against each level of density
in $C(\Delta_{C})$ at each level of population $\gamma$. Here we only present the
results of three population $\rho = (0.0, 0.2, 0.5)$ (moving horizontally
from top to bottom in the rows of graphs) and three $\gamma = (0.2, 0.5,$
1.0) (moving vertically from left to right in the columns of graphs)
due to space limitations. Green and red lines represent the sample
mean of the estimated $\rho$ with specification of error standard devi-
ation of $\sigma = 1.0$ and $\sigma = 0.1$ respectively, and bars represent upper
and lower bounds of the 95% confidence interval around the mean.
Asterisks indicate that the upper bounds of the 95% confidence
interval fall below the given population value of $\rho$, indicating that
the sampling distribution of $\rho$ exhibits a negative bias (Mizruchi
and Neuman, 2008). The black line represents a population target
value of $\rho$, but is frequently intertwined with the $\sigma = 0.1$ (red) curve,
which indicates the mean sample estimates for $\rho$ appear to be very
close to the values of the specified population parameter at almost
all levels of density across each level of population $\rho$ and popula-
tion $\gamma$. When $\sigma = 1.0$ (green lines) in Fig. 3, the results show that
negative bias is dependent on the value of $\gamma$ such that negative
bias occurs primarily when the effect of event participation, $\gamma$, is
small (graphs on the left rather than those on the right). This effect is
almost invariant across the levels of $\rho$.

Table 1 presents fit statistics, means and 95 percent confidence
intervals, for the $\rho$ estimates by levels of density and $\gamma$. The data
show that as $\gamma$ increases the $\rho$ estimates stabilize across various
density levels thus reducing the estimate bias.

At the highest ends of the density, across all three levels of
population $\rho$ for each value of $\gamma$, the degree of negative bias is
quite high. For example, densities 0.85 or higher indicate that the
average number of co-participated events is greater than 8.61 (the
corresponding estimated $\lambda$) out of maximum event size $K = 10$. At
this level the autocorrelation parameter underestimated affiliation
influence significantly.

7.1. Regression analysis

We have also conducted a regression analysis to statistically
test the effect of the population $\gamma$ value on bias in estimated $\rho$,
using our simulation results of $K = 10$ and $\sigma = 1.0$. We computed the
difference between estimated $\rho$ and the population $\rho$ (estimated $\rho -$ population $\rho = \Delta \rho$) to evaluate the level of bias, and regressed it
on density, population $\gamma$ and population $\rho$ values. Here, we report
only the magnitude of the effect size in order to evaluate the bias
and do not report significance level since the “statistically signifi-
cant” results are most likely an artifact of the large sample size
(N = 81,800). The results show that the standardized coefficient for
density effect was –0.23, which indicates that the negative bias in
$\rho$ becomes greater as density increased. Findings were consistent
with those reported in Neuman and Mizruchi (2010). The stan-
dardized coefficient for the $\gamma$ effect was 0.17, which indicates that
the positive bias in $\rho$ becomes greater as the population level of $\gamma$
increased. These results suggest that increase in negative bias in $\rho$
with higher density level can be offset by the increase in positive
bias in $\rho$ with higher values in $\gamma$. The stronger the effect of the diago-
nal, the greater the likelihood that it can cancel out the negative bias
in the autocorrelation parameter. Thus the event participation posi-
tive bias helps counteract the density negative bias. The effect size
for the population effect $\rho$ was 0.05, which indicates the positive
bias in $\rho$ becomes greater as the population $\rho$ increases. However,
this effect size is very close to zero and hence has a negligible influ-
ence. In supplementary analyses, we included an interaction term
of density and population effect $\rho$ to statistically test if the negative
bias in $\rho$ at higher levels of density increased at increasing levels of
population $\rho$ (Mizruchi and Neuman, 2008). The result showed that
the standardized coefficient for the interaction effect was 0.02,
which indicates virtually no effect. The results were also consistent
with those in Neuman and Mizruchi (2010) that did not support
the existence of the interaction effect.

7.2. Sensitivity analysis

We repeated the simulation analysis for $K = 20$ to compare with
the results of the simulation with $K = 10$. For this simulation the $A$
(affiliation) matrix is a 100-actor by 20-events affiliation matrix,
and 100 random bipartite graphs were generated for each of the
18 target density levels in $C, \Delta_{C} = \{0.05, 0.10, 0.15, 0.20, 0.25, 0.30,$
0.35, 0.40, 0.45, 0.50, 0.55, 0.60, 0.65, 0.70, 0.75, 0.80, 0.85, 0.90\}
using the corresponding estimated $\lambda$ values \{3.54, 4.98, 6.08, 7.07,
7.89, 8.66, 9.39, 10.05, 10.64, 11.22, 11.81, 12.43, 12.95, 13.54, 14.08,
14.66, 15.13, 15.71\} (refer to Fig. 1). We reproduced the baseline
model, that is, a model with three $X$ variables plus an intercept term,
and specified the standard error of the residuals to be either $\sigma = 1.0$
or $\sigma = 0.1$. We selected the same population values for $\rho = (0.0, 0.2,$
0.5) and $\gamma = (0.2, 0.5, 1.0)$ to facilitate comparison with the $K = 10$
case. Fig. 4 shows the equivalent graphs for the specification of
$K = 20$ case and Table 2 presents the corresponding statistics.

Fig. 3 shows a similar pattern of results produced in the $K = 10$
case. It is interesting to note that the negative bias when $\sigma = 1.0$ is
weaker in the lower densities in the $K = 20$ case than in the $K = 10$
case. This occurs because of the shift in skewness of the Poisson
distribution as greater values of $\lambda$ are employed in the case of $K = 20$, from being left-skewed to being more symmetric around the mean.
Additionally, for all levels of $\gamma$, strong negative bias starts around
a density level of .85 (estimated $\lambda = 15.13$) for each target $\rho$ value.
This negative bias again disappears when the standard deviation of
the error term returns to the $\sigma = 0.1$ scenario. It is also worth
noting that the one effect we did not observe in either case but was
observed by Mizruchi and Neuman (2008) was a dependence on $\rho$
on the magnitude of the bias.

In summary, our results are consistent with the previous
Mizruchi and Neuman one-mode simulation\footnote{They also specified that three $X$ plus constant with values of $K, \beta$, and $\epsilon$ were
drawn from standard normal distributions for their baseline model.} in that a significant bias in the estimates for $\rho$ becomes more pronounced as network
density increases. However, our results were not consistent with their observation that the negative bias tendency became more
pronounced at higher values of population $\rho$. More specifically (for
the $\sigma = 1.0$ scenario), Mizruchi and Neuman (2008) found that a signif-
ican bias starts at densities as low as 0.05 for $\rho = 0.5$ but it did
not start until the density reached 0.20 for $\rho = 0.0$. One possible
explanation for the divergence of findings is that the addition of
$D$ (the diagonal count of the number of events) to our regression
model adds information that consequently reduces the proportion
of disturbance in the model (it increases model fit) since $D$ is essen-
tially the out-degree of the corresponding row the $W$ matrix\footnote{Another possible reason would come from the difference in how the $W$ matrix is
defined. Mizruchi and Neuman used a random graph with a given target density,
while we generated random bipartite graph assuming Poisson outdegree dis-
tribution and multiplied it by its transpose. Such differences in the distribution may
account for the differing results.} and thus is a count of the number of disturbance terms. This addi-
tional information may reduce variances in the iterative maximum
likelihood optimization process of the linear network autocorrela-
tion model, and acts to counter the $\rho$-dependent bias observed by
Mizruchi and Neuman (2008). In other words, the two-mode esti-
information case provides additional information \((D)\) from the network data thus making network effects estimation more accurate.

8. Conclusion

We have introduced a two-mode version of the network autocorrelation model by developing a new influence model of “Affiliation Exposure,” potentially opening up new network analysis opportunities for datasets which lack traditional friendship network data. In addition to the alternate formulation of \(W\), the two-mode network autocorrelation model is distinguished from its one-mode counterpart by the inclusion of \(D\) (the diagonal of the \(W\) matrix) and the corresponding estimation of \(\gamma\) in the regression equation. Our simulation analysis based on Poisson outdegree distributions (chosen because of the appearance of this distribution in several real-world datasets) has shown that the two-mode network autocorrelation model has similar statistical properties to the one-mode version (i.e., negative bias in \(\rho\) becoming stronger with higher density). However, the degree of this bias, unlike the one-mode case, was independent of the true population value \((\rho)\). Additionally, the simulation results have shown that stronger \(D\) terms helped to reduce the observed tendency of the negative estimation bias to increase with density. Combining these results together, the additional structure of \(D\) may serve to help stabilize the estimates in the presence of noise as part of the maximum likelihood optimization process, and thus acts to counter the \(\rho\)-dependent bias observed by others in single-mode networks, but further research will be needed to confirm this.

Substantively, special attention is needed when the average number of events each actor participated in is high. When our two-mode version of the network autocorrelation model exceeds a \(\Delta\) of 0.80 in the co-membership matrix, the autocorrelation parameter tends to be severely underestimated. Consequently, estimating network effects when participation in events is exceedingly high may be biased. For example, when attendance at community events by community leaders is near universal, estimating social influences may be problematic and underestimated. Methodologically, our simulation results were obtained by generating random bipartite graphs based on Poisson outdegree distributions. Future research will be expanded by generating random bipartite graphs with other distributional assumptions, such as such as exponential or power-law distributions, as well as using joint distribution of in-degree and out-degree distributions if they are known. Finally, this simulation study has shown that one of the possible solutions to attenuate the negative bias as a function of density would be to include meaningful information from the social influence weight.

![Fig. 4. Mean plots of the estimated autocorrelation parameter \(\rho\) among 100 replications against each level of density in \(C(\Delta_{\rho})\) at each level of population \(\gamma\). Bars represent upper and lower bounds of the 95% confidence interval around the mean. Asterisks indicate that upper bound of the 95% confidence interval fall below the given population value of \(\rho\). Event size was specified as 10 \((K=20)\). \(\Delta_{\rho} = 0.05, 0.10, 0.15, 0.20, 0.25, 0.30, 0.35, 0.40, 0.45, 0.50, 0.55, 0.60, 0.65, 0.70, 0.75, 0.80, 0.85, 0.90\) where the corresponding estimated \(\Delta\) values are \(\{3.54, 4.98, 6.08, 7.07, 7.89, 8.66, 9.39, 10.05, 10.64, 11.22, 11.81, 12.43, 12.95, 13.54, 14.08, 14.66, 15.13, 15.71\}\).]
matrix in a regression model. Including this additional information might mitigate the influence of noise in the model. Our two-mode version of network autocorrelation model has shown the utility of such method by including the diagonal values of the converted matrix in an autocorrelation model. This method may be applied to the one-mode case where the diagonal information of the influence weight matrix is meaningful, but further research is needed to confirm the utility of this approach as well. In conclusion, we find that network influence estimates can be validly obtained from two-mode network data and that the affiliation exposure may become an important method used to understand how co-participation influences social norms, attitudes, and behaviors.
